FREE  
Webinar:

Should

I use (https://bit.ly  
React /react-vs-  
or vue)  
Vue?

This is the last part of a three-part tutorial to build an employee management web app, named Project Dream Team. In

Part Two (<https://scotch.io/tutorials/build-a-crud-web-app-with-python-and-flask-part-two>)

of the tutorial, we built out the CRUD functionality of the app.

We created forms, views, and templates to list, add, edit and delete departments and roles.

By the end of Part Two, we could assign (and re-assign) departments and roles to employees.

**10 React apps for real-world practice.**

(<https://bit.ly/2C8NpYC>)

In Part Three, we will  
cover:

Table of Contents

- # Conclusion

1. » Custom error pages
2. » Unit tests
3. » Deployment on PythonAnywhere

## # Custom Error Pages

Web applications make use of HTTP errors to let users know that

something has gone  
wrong. Default error  
pages are usually quite  
plain, so we will create  
our own custom ones  
for the following  
common HTTP errors:

1. » 403 Forbidden:  
this occurs when a  
user is logged in  
(authenticated), but  
does not have  
sufficient  
permissions to  
access the resource.  
This is the error we  
have been throwing  
when non-admins  
attempt to access an  
admin view.
2. » 404 Not Found:  
this occurs when a  
user attempts to  
access a non-  
existent resource

such as an invalid

URL, e.g

```
http://127.0.0.1:5000  
/nothngere
```

.

### 3. » 500 Internal

Server Error: this is a general error thrown when a more specific error cannot be determined. It means that for some reason, the server cannot process the request.

We'll start by writing the views for the custom error pages. In your `app/__init__.py` file, add the following code:

```
PYTHON
```

```
# app/__init__
```

```
# update import  
from flask imp
```

```
# existing coo
```

```
def create_app
```

```
# existing
```

```
@app.error  
def forbid  
    return
```

```
@app.error  
def page_4  
    return
```

```
@app.error  
def inter
```

```
        return  
    return app
```

We make use of Flask's

```
@app.errorhandler
```

decorator to define the error page views, where we pass in the status code as a parameter.

Next, we'll create the template files. Create a

```
app/templates/errors
```

directory, and in it,

create `403.html` ,  
`404.html` , and `500.html` .

```
HTML  
  
<!-- app/tempi
```

```
{% extends "base.html" %}
{% block title %}{{ title }}{% endblock %}
{% block body %}
<div class="container">
  <div class="row">
    <div class="col-md-12">
      <div class="card">
        <div class="card-header">
          <h3>{{ title }}</h3>
        </div>
        <div class="card-body">
          <div class="row">
            <div class="col-md-6">
              <div class="form-group">
                <input type="text" value="{{ name }}" />
              </div>
            </div>
            <div class="col-md-6">
              <div class="form-group">
                <input type="text" value="{{ email }}" />
              </div>
            </div>
          </div>
          <div class="form-group">
            <input type="text" value="{{ password }}" />
          </div>
          <div class="form-group">
            <input type="text" value="{{ confirm_password }}" />
          </div>
          <div class="form-group">
            <input type="button" value="Sign Up" />
          </div>
        </div>
      </div>
    </div>
  </div>
</div>
{% endblock %}
```

## HTML

```
<!-- app/templates/

{% extends "base.html" %}
{% block title %}
{% block body %}
<div class="container">
  <div class="row">
    <div class="col-md-12">
      <div class="card">
        <div class="card-header">
          <h1>
        </h1>
        <div class="card-body">
          <h2>
        </h2>
        <div class="card-text">
          <p>
        </p>
        </div>
      </div>
    </div>
  </div>
</div>
```

```
{% endblock %}
```

*HTML*

```
<!-- app/temp:
```

```
{% extends "base.html" %}
```

```
{% block title
```

```
{% block body
```

```
<div class="co
```

```
<div class=''
```

<div class

 $\langle \text{div } cl_i$ 

<div s

<

<

<

```
</div>  
</div>  
</div>  
</div>  
</div>  
</div>  
{% endblock %}
```

All the templates give a brief description of the error, and a button that links to the homepage.

Run the app and log in as a non-admin user, then attempt to access

`http://127.0.0.1:5000`  
`/admin/departments`

. You should get the following page:

vanilla

JavaScript

👉 React

Now attempt to access  
this non-existent page:

`http://127.0.0.1:5000  
/nothinghere`

. You should see:

To view the internal server error page, we'll create a temporary route where we'll use Flask's `abort()` function to raise a 500 error. In the `app/__init__.py` file, add the following:

```
PYTHON

# app/__init__
```

```
# update import
from flask import

# existing code

def create_app():
    # existing code

@app.route('/')
def error():
    abort(404)

return app
```

Go to

<http://127.0.0.1:5000/500>

; you should see the  
following page:

Now you can remove the temporary route we just created for the internal server error.

## # Tests

Now, let's write some tests for the app. The importance of testing software can't be overstated. Tests help

ensure that your app is working as expected, without the need for you to manually test all of your app's functionality.

We'll begin by creating a test database, and give the database user we created in

Part One (<https://scotch.io/tutorials/build-a-crud-web-app-with-python-and-flask-part-one>) all privileges on it:

```
BASH
```

```
$ mysql -u root -p
```

```
mysql> CREATE DATABASE test;
```

```
Query OK, 1 row affected
```

```
mysql> GRANT A  
Query OK, 0 ro
```

Now we need to edit the `config.py` file to add configurations for testing. Delete the current contents and replace them with the following code:

```
PYTHON  
  
# config.py  
  
class Config(  
    """  
    Common con  
    """
```

```
DEBUG = True
```

```
class Developer:
```

```
    """
```

```
    Developer
```

```
    """
```

```
SQLALCHEMY
```

```
class Product:
```

```
    """
```

```
    Production
```

```
    """
```

```
DEBUG = False
```

```
class Testing:
```

```
    """
```

```
    Testing co
```

```
    """
```

```
        TESTING = True

    app_config = ConfigDict.from_mapping(
        {
            'development': DevelopmentConfig,
            'production': ProductionConfig,
            'testing': TestingConfig,
        }
    )
```

We have put

`DEBUG = True` in the base class, `Config`, so that it is the default setting.

We override this in the `ProductionConfig` class.

In the `TestingConfig` class, we set the `TESTING` configuration variable to `True`.

We will be writing unit tests. Unit tests are written to test small, individual, and fairly

isolated units of code,  
such as functions. We  
will make use of  
Flask-Testing  
(<https://pythonhosted.org/Flask-Testing/>)  
, an extension that  
provides unit testing  
utilities for Flask.

*BASH*

```
$ pip install
```

Next, create a `tests.py`  
file in the root directory  
of your app. In it, add  
the following code:

```
PYTHON
```

```
# tests.py
```

```
import unittest
```

```
from flask_test
```

```
from app import
```

```
from app.model
```

```
class TestBase
```

```
    def create
```

```
        # pass
```

```
        config
```

```
        app =
```

```
        app.co
```

```
            S
```

```
        )
```

```
        return
```

```
def setUp():
    """
    Will be called before each test
    """

    db.create_all()

    # create an admin user
    admin = User(username='admin', password='admin')

    # create an employee user
    employ = User(username='employee', password='employee')

    # save the users to the database
    db.session.add(admin)
    db.session.add(employ)
    db.session.commit()

def tearDown():
    """
    Will be called after each test
    """
```

```
        db.session.add(user)
        db.session.commit()

    if __name__ == '__main__':
        unittest.main()
```

In the base class above, `TestBase`, we have a `create_app` method, where we pass in the configurations for testing.

We also have two other methods: `setUp` and `tearDown`. The `setUp` method will be called automatically before every test we run. In it, we create two test users, one admin and one non-admin, and save them to the database. The

`tearDown` method will be called automatically after every test. In it, we remove the database session and drop all database tables.

To run the tests, we will run the `tests.py` file:

```
BASH

$ python tests.py

-----
Ran 0 tests in

OK
```

The output above lets us know that our test setup is OK. Now let's write

some tests.

```
PYTHON
```

```
# tests.py
```

```
# update import
```

```
import os
```

```
from flask imp
```

```
from app.model
```

```
# add the fol
```

```
class TestMode
```

```
def test_e
```

```
"""
```

```
Test i
```

```
"""
```

```
        self.assertEqual(1, len(departments))

    def test_create_department(self):
        """
        Test that a new department can be created.
        """

        # create a new department
        department = Department(name="New Department")

        # save the department to the database
        db.session.add(department)
        db.session.commit()

        self.assertEqual(2, len(departments))

    def test_create_role(self):
        """
        Test that a new role can be created.
        """

        # create a new role
        role = Role(name="New Role")
```

```
        # save
        db.session.add(todo)
        db.session.commit()

        self.flash('New item successfully added.')

class TestViews:

    def test_index(self):
        """
        Test that the index page loads without
        errors
        """
        response = self.client.get('/')
        self.assertEqual(response.status_code, 200)

    def test_new(self):
        """
        Test that the new page loads without
        errors
        """
        response = self.client.get('/new')
        self.assertEqual(response.status_code, 200)

    def test_create(self):
```

```
        """
        Test to ensure that the user can login
        and receive a redirect to the home page
        """
        target_url = "/home"
        redirect_url = "/home"
        response = self.client.get(target_url)
        self.assertEqual(response.status_code, 200)

def test_create_user(self):
    """
    Test to ensure that a user can be created
    and receive a redirect to the home page
    """
    target_url = "/create"
    redirect_url = "/home"
    response = self.client.post(target_url, data={
        "username": "test",
        "password": "test"
    })
    self.assertEqual(response.status_code, 200)

def test_delete_user(self):
    """
    Test to ensure that a user can be deleted
    and receive a redirect to the home page
    """
```

```
        and re

        """

        target

        redire

        respon

        self.a

        self.a

def test_c

    """

    Test a

    and re

    """

    target

    redire

    respon

    self.a

    self.a

def test_l

    """

    Test a

    and re

    """
```

```
        target = request.args.get('target')
        redirect_url = target if target else None
        response = self.redirect(redirect_url)
        return self.response(response)
```

```
def test_redirect(self):
    """
    Test that the redirect endpoint
    and redirect method work as expected.
    """
    target = 'http://example.com'
    redirect_url = self.redirect(target)
    response = self.get_response(redirect_url)
    self.assertEqual(response.status_code, 302)
    self.assertEqual(response.headers['Location'], target)
```

```
class TestErrorHandling(unittest.TestCase):
```

```
    def test_404(self):
        # create a client
        @self.app.route('/404')
        def four_oh_four():
```

```
        al

    respon

    self.a

    self.a

def test_
    respon

    self.a

    self.a

def test_
    # crea

    @self.

    def in

        al

    respon

    self.a

    self.a

if __name__ ==
    unittest.r
```

We've added three

```
classes: TestModels ,  
TestViews and  
TestErrorPages .
```

The first class has methods to test that each of the models in the app are working as expected. This is done by querying the database to check that the correct number of records exist in each table.

The second class has methods that test the views in the app to ensure the expected status code is returned. For non-restricted views, such as the homepage and the login page, the `200 OK` code

should be returned; this means that everything is OK and the request has succeeded. For restricted views that require authenticated access, a `302 Found` code is returned. This means that the page is redirected to an existing resource, in this case, the login page. We test both that the `302 Found` code is returned and that the page redirects to the login page.

The third class has methods to ensure that the error pages we created earlier are shown when the respective error occurs.

Note that each test

method begins with `test`. This is deliberate, because `unittest`, the Python unit testing framework, uses the `test` prefix to automatically identify test methods. Also note that we have not written tests for the front-end to ensure users can register and login, and to ensure administrators can create departments and roles and assign them to employees. This can be done using a tool like Selenium Webdriver (<http://www.seleniumhq.org/projects/webdriver/>); however this is outside the scope of this tutorial.

Run the tests again:

```
BASH

$ python tests.py
.....
-----
Ran 14 tests

OK
```

Success! The tests are passing.

## # Deploy!

Now for the final part of the tutorial: deployment. So far, we've been running the app locally. In this

stage, we will publish the application on the internet so that other people can use it. We will use PythonAnywhere (<https://www.pythonanywhere.com>), a Platform as a Service (PaaS) that is easy to set up, secure, and scalable, not to mention free for basic accounts!

## PythonAnywhere Set-Up

Create a free PythonAnywhere account [here](https://www.pythonanywhere.com/registration/register/beginner/) (<https://www.pythonanywhere.com/registration/register/beginner/>) if you don't already have one. Be sure to select your username carefully since the app will be

accessible at

`your-  
username.pythonanywhere.com`

.

Once you've signed up,

`your-  
username.pythonanywhere.com`

should show this page:

We will use git to upload  
the app to  
PythonAnywhere. If  
you've been pushing  
your code to cloud

repository management

systems like

Bitbucket

(<https://bitbucket.org/>)

,

Gitlab

(<https://about.gitlab.com/>)

or Github ([github.com/](https://github.com/)),

that's great! If not,

now's the time to do it.

Remember that we

won't be pushing the

`instance` directory, so

be sure to include it in

your `.gitignore` file, like

so:

```
BASH
```

```
# .gitignore
```

```
*.pyc
```

```
instance/
```

Also, ensure that your `requirements.txt` file is up to date using the `pip freeze` command before pushing your code:

Now, log in to your PythonAnywhere account. In your dashboard, there's a `Consoles` tab; use it to start a new Bash console.

In the PythonAnywhere  
Bash console, clone  
your repository.

*BASH*

```
$ git clone https://github.com/
```

Next we will create a  
virtualenv, then install  
the dependencies from

the `requirements.txt` file. Because PythonAnywhere installs `virtualenvwrapper` (<https://virtualenvwrapper.readthedocs.io/en/latest/>) for all users by default, we can use its commands:

*BASH*

```
$ mkvirtualenv  
$ cd project-c  
$ pip install
```

We've created a `virtualenv` called `dream-team`. The `virtualenv` is automatically activated. We then entered the

project directory and  
installed the  
dependencies.

Now, in the Web tab on  
your dashboard, create  
a new web app.

Select the Manual  
Configuration option  
(**not** the Flask option),  
and choose Python 2.7  
as your Python version.  
Once the web app is

created, its  
configurations will be  
loaded. Scroll down to  
the Virtualenv section,  
and enter the name of  
the virtualenv you just  
created:

## Database Configuration

Next, we will set up the  
MySQL production  
database. In the

Databases tab of your  
PythonAnywhere  
dashboard, set a new  
password and then  
initialize a MySQL  
server:

The password above will  
be your database user  
password. Next, create a  
new database if you  
wish. PythonAnywhere  
already has a default  
database which you can

use.

By default, the database user is your username, and has all privileges granted on any databases created. Now, we need to migrate the database and populate it with the tables. In a Bash console on PythonAnywhere, we will run the

```
flask db upgrade
```

command, since we already have the migrations directory that we created locally. Before running the commands, ensure you are in your virtualenv as well as in the project directory.

*BASH*

```
$ export FLASK_APP=your-app.py
$ export FLASK_ENV=development
$ export SQLAlchemy_DATABASE_URI='sqlite:///your-app.db'
$ flask db upgrade
```

When setting the `SQLALCHEMY_DATABASE_URI` environment variable, remember to replace `your-username` ,

`your-password` ,  
`your-host-address` and  
`your-database-name` with  
their correct values. The  
username, host address  
and database name can  
be found in the MySQL  
settings in the  
Databases tab on your  
dashboard. For  
example, using the  
information below, my  
database URI is:

```
mysql://projectdreamteam:passwor  
services.com/projectdreamteam$dr
```

## WSGI File

Now we will edit the WSGI file, which PythonAnywhere uses to serve the app. Remember that we are not pushing the `instance` directory to version control. We therefore need to configure the environment variables for production, which we will do in the WSGI file.

In the Code section of the Web tab on your dashboard, click on the link to the WSGI configuration file.

Delete all the current contents of the file, and replace them with the following:

```
PYTHON
```

```
import os
```

```
import sys
```

```
path = '/home,
```

```
if path not in
    sys.path.append

os.environ['FLASK_CONFIG'] = 'development'
os.environ['SECRET_KEY'] = 'secret-key'
os.environ['SQLALCHEMY_DATABASE_URI'] = 'sqlite:///'

from run import app
```

In the file above, we tell PythonAnywhere to get the variable `app` from the `run.py` file, and serve it as the application. We also set the `FLASK_CONFIG`, `SECRET_KEY` and `SQLALCHEMY_DATABASE_URI` environment variables. Feel free to alter the secret key. Note that the `path` variable should contain your username and project directory

name, so be sure to  
replace it with the  
correct values. The same  
applies for the database  
URI environment  
variable.

We also need to edit our  
local `app/__init__.py` file  
to prevent it from  
loading the  
`instance/config.py` file  
in production, as well as  
to load the  
configuration variables  
we've set:

```
PYTHON

# app/__init__

# update impor
```

```
import os

# existing code

def create_app():
    if os.geteuid() == 0:
        app = Flask(__name__)
        app.config.from_object(Config)
        app.register_blueprint(bp)
        return app
    else:
        app = Flask(__name__)
        app.config.from_object(Config)
        app.register_blueprint(bp)
        return app

# existing code
```

Push your changes to version control, and pull them on the PythonAnywhere Bash console:

Now let's try loading the app on PythonAnywhere. First, we need to reload the app on the Web tab in the dashboard:

Now go to your app

URL:

Great, it works! Try  
registering a new user  
and logging in. This  
should work just as it  
did locally.

## Admin User

We will now create an admin user the same way we did locally. Open the Bash console, and run the following commands:

```
BASH
```

```
$ flask shell
```

```
>>> from app.i
>>> from app
>>> admin = Er
>>> db.session
>>> db.session
```

Now you can login as an admin user and add departments and roles, and assign them to employees.

www.akajlm.net
